This paper describes the SDMLib solution to the Class Responsibility Assignment Case for TTC2016. SDMLib provides reachability graph computation ala Groove. Thus, the simple idea was to provide rules for possible clustering operations and then use the reachability graph computation to generate all possible clusterings. Then, we apply the CRAIndex computation to each generated clustering and identify the best clustering. Of course, this runs into scalability problems, very soon. Thus, we extended our reachability graph computation to do an A* based search space exploration. Therefore, we passed the CRAIndex computation as a metric to our reachability graph computation and in each step, we consider the set of not yet expanded graphs and choose the one, that has the best metric value for expansion. The paper reports about the results we achieved with this approach.

1 Introduction

This paper describes the SDMLib solution to the Class Responsibility Assignment Case for TTC2016 [1]. SDMLib provides *reachability graph computation* ala Groove [2]. For a given start graph and a given set of rules, the reachability graph computation generates all graphs that may be derived from the start graph by applying all rules at all possible matches as often as possible in all possible orders. Each time a new graph is computed, we search through the set of already computed graphs for an already known isomorphic graph. As proposed by [2], SDMLib computes node and graph certificates which are then used as hash keys to access potentially isomorphic graphs efficiently. The node certificates then also help to do the actual isomorphism test. If a new graph has been generated, we create a so-called *reachable state node* and we connect the reachable state node of the predecessor graph with the reachable state node for the new graph via a rule application edge labeled with the name of the rule used. In addition, a root node of the graph is attached to the reachable state node. Altogether, the generated reachability graph has a top layer consisting of reachable state nodes connected via rule application edges and each reachable state node refers to the corresponding application graph via a `graphRoot` link. In SDMLib, this whole structure is again a graph, and graph rules may be applied to it in order to find e.g. reachable states with a maximal metric value for the attached application graph or to find states where all successor states have lower metric values or to find the shortest path leading to the best state. Actually, any graph related algorithm may be deployed.

The Class Responsibility Assignment Case challenges the rule orchestration mechanisms provided by the different model transformation approaches. Thus, our solution uses the SDMLib reachability graph computation for rule orchestration. This is a very simple way to apply all rules in all possible ways and in addition we are able to investigate all intermediate results in order to identify which paths through the search space are the most interesting ones. The drawback of this approach is that it wastes a lot of runtime and memory space for copying the whole class model graph each time a rule is applied and for the search of already known isomorphic copies of the generated graphs. As shown in the case description, the number

of possible clusterings grows with the Bell number, i.e. for larger examples a complete enumeration of all possible clustering is not possible in a meaningful time. As only a small fraction of the search space can be explored, it might be helpful to be able to investigate all intermediate states to identify the most promising spots for further expansion. Thus, we hope that the flexibility provided by the SDMLib reachability graphs to investigate different intermediate states pays off, in the end.

As it is usually not possible to generate the whole reachability graph for a given example, our reachability graph computation may be restricted to a maximum number of reachable states to be generated. Next, we have extended our reachability graph computation with an A* like search space exploration that takes a metric as parameter and at each step chooses the state with the best metric value for expansion. We have developed two variants of this A* algorithm which will be discussed below.

The next section introduces the rules we use to solve the Class Responsibility Assignment Case and then Section 3 shows the different search strategies we use in this example. Finally, Section 4 shows our performance measurements.

2   The Model Transformation Rules

Our feature clustering approach uses two SDMLib model transformation rules. In the preparation phase we use the rule shown in Figure 1 to create one class for each feature in our class model.

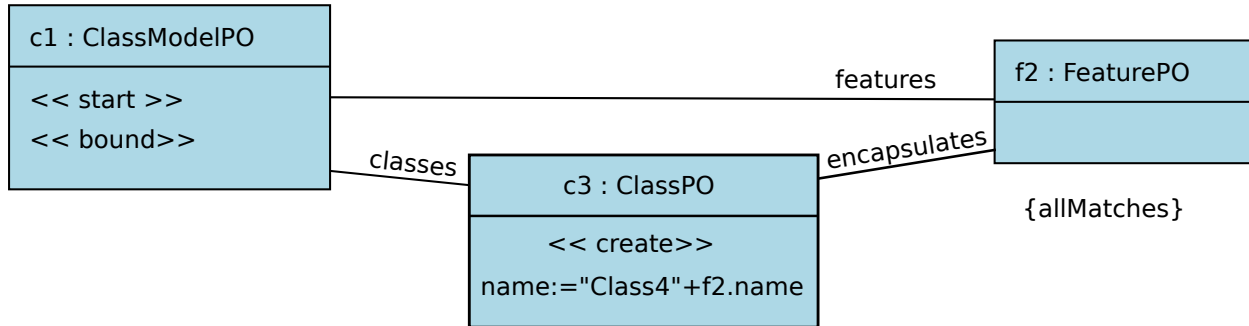

Figure 1: Rule adding initial classes

This rule starts by matching the pattern object `c1` to the `ClassModel` object passed as parameter. Then, `f2` is matched to a Feature object attached to this `ClassModel` object. The {`allMatches`} constraint causes the rule to be applied to all possible matches. Thus, for each `Feature` object in our current `ClassModel`, the <<`create`>> sterotype on pattern object `c3` causes the creation of a new `Class` object. In addition the new `Class` object is attached to the `ClassModel` via a `classes` link and to the `Feature` object via an `encapsulates` link. Finally, the new `Class` object's `name` attribute gets assigned the concatenation of the prefix `"Class4"` and the `name` of the current `Feature`. Thus, after the execution of this rule, each feature has its own class containing just this feature. This class model is then used as starting point for the repetitive application of our clustering rule.

Our clustering rule merges classes along functional or data dependencies, cf. Figure 2. The matching of this rule starts with the `ClassModel` object which is bound to `c1` at rule invocation. Then we follow a `classes` edge to find a match for `c2`, i.e. a `Class` object in our `ClassModel`. Next, we follow an `encapsulates` edge to match a `Method` object `m4` contained in `c2`. The object matched by `m4` must have a `dataDependency` edge or a `functionalDependency` edge to a `Feature` object matched by the pattern
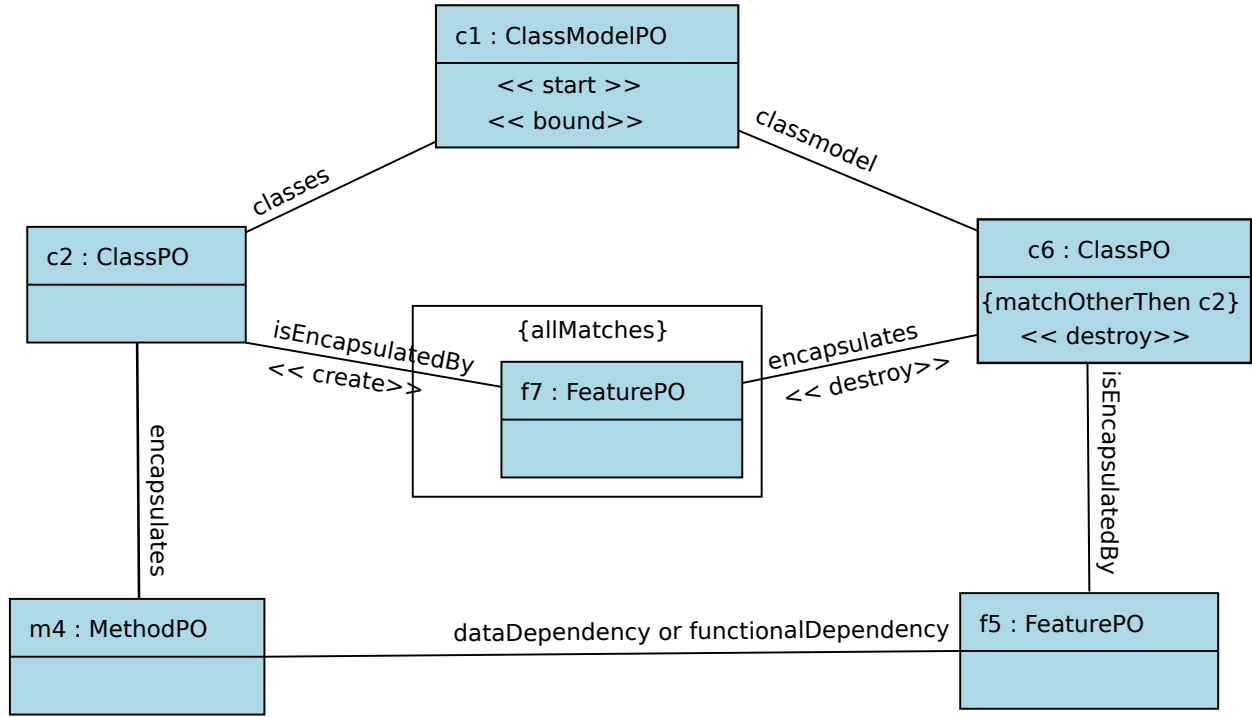

c1 : ClassModelPO

Figure 2: Merging Classes via Feature Dependencies

object f5. This Feature object in turn must be contained in a Class matched by c6. By default, SDM-Lib allows homomorphic matches, thus c2 and c6 would be allowed to match the same Class object. Via the {matchOtherThen c2} clause, we enforce isomorphic matching, i.e. c2 and c6 must match two different Class objects. Finally, the Class matched by c6 must belong to our ClassModel c1. When such a match is found, the subpattern containing the FeaturePO pattern object f7 is executed on all possible matches. Pattern object f7 matches for all features contained in the Class matched by c6. (Note, f7 exploits homomorphic matching and will also match the Feature object already matched by f5.) For each Feature object, the encapsulates edge connecting it to the Class matched by c6 is deleted and a new isEncapsulatedBy edge connecting it to the Class matched by c2 is created. After transferring all features to the Class matched by c2, the Class matched by c6 is destroyed. Thus, the rule shown in Figure 2 merges two classes that are connected via a feature dependency into one class.

Our clustering rule merges classes only if there is a dependency between them. This already utilizes application specific knowledge about our CRAIndex metric. Our search space expansion will start with classes containing only one feature each. Merging classes without a dependency between them is not going to improve the CRAIndex of the resulting class model. Merging classes has the potential to improve the CRAIndex only if the classes contain features that depend on each other. Thus, our clustering rule is already optimized for the optimization of the CRAIndex. Using a different metric would perhaps require a more general clustering strategy. As the metric is evaluated during the search space exploration, it would be easy to simply merge any two classes, as any graphs resulting from applying a non metric improving rule would immediately be dismissed anyways.

3   The Search Space Exploration Mechanisms

At the beginning, a `ReachbilityGraph` object is initialized with a start graph or `startState` and with a set of `rules` that shall be applied to the different reachable states. Our standard A* search space exploration algorithm is shown in Listing 1. For the A* search space exploration, we call e.g.

```
rg.explore(25000, g -> CRAIndexCalculator.calculateCRAIndex((ClassModel) g));
```

where the first parameter is the maximal number of states to be generated and the second parameter is the metric function that guides our search space expansion algorithm. First, our expansion algorithm initializes its `todo` list with the `startState` and adds the `startState` to a hash table of reachable `states` where a graph `certificate` is used as key, as proposed by [2]. Then, line 5 loops through the `todo` list until it drains or the maximal `depth` of the search space is reached. Line 6 of our explore method just `sorts` the `todo` list before choosing a new element in line 7. Thereby, each exploration step considers the state with the best CRAIndex for further expansion resulting in a depth first like expansion strategy. Then line 8 and line 9 iterate through all `rules` and all matches. For each match, we `clone()` the `current` state and `apply()` the rule changes to that clone, resulting in a `newState`. As the `newState` may have been created by other rule applications already, line 11 tries to `find` an `isoOldState`, i.e. the `find` operation computes the `certificate` of the `newState` and tries to look it up in the `states` hash table. This involves an isomorphism check to exclude accidentally matching certificates. If no `isoOldState` is found, line 13 adds the `newState` to the hash table of reachable `states`, line 14 adds an edge labeled with the applied rule from the `current` state to the `newState`, and line 15 adds the `newState` to our `todo` list. If there is an `isoOldState` line 17 just adds an edge from the `current` state to the `isoOldState`.

```
 1  ReachabilityGraph :: explore(depth, metric) {
 2      todo = new ArrayList();
 3      todo.add(this.startState);
 4      states.put(certificate(this.startState), startState);
 5      while (! todo.isEmpty() && states.size() <= depth) {
 6          sort(todo, metric);
 7          current = todo.get(0); todo.remove(0);
 8          for(Rule r : this.rules) {
 9              while (r.findMatch()) {
10                  newState = current.clone().apply(r);
11                  isoOldState = find(states, newState);
12                  if (isoOldState == null){
13                      states.put(certificate(newState), newState);
14                      addEdge(current, r, newState);
15                      todo.add(newState);
16                  } else {
17                      addEdge(current, r, isoOldState);
18                  }
19              }
20          }
21      }
22  }
```

Listing 1: Default A* based Search Space Expansion

Within each step, our default A∗ search space exploration strategy generates all successors of the `current` state. For case E there are about 400 dependencies, thus, the initial state has about 400 successor states. While this number decreases by one with each rule application, the first 100 rule applications have 350 successors on average resulting in 35000 states, which already exceeds our memory space. To improve this, we added a variant of our algorithm called *Ignore Decline* mode. The Ignore Decline mode improves our exploration algorithm by comparing the metric value of the `newState` with the current `bestMetric`. If the metric of the `newState` is lower then the `bestMetric` we ignore the `newState`, i.e. we do not add it to our reachability graph nor to our `todo` list. This may exclude some important candidates from later consideration but it reduces the number of states to be added to our reachability graph considerably thus reducing memory space consumption.

The second variant of our search space exploration algorithm is called *Promote Improvements* mode. The Promote Improvement mode computes the metric for each new state and in case of an improvement compared to the current state, we stop the expansion of the current state (putting it back into the todo list). Then we jump back to line 6 and start with a new iteration, i.e. we sort the todo list (bringing the new best state to the front) and continue the search space exploration with this new state. The Promote Improvement mode reaches local optima of the reachability graph very fast. Note, when the search is exhausted for some state and we go back to earlier states, rule application on those earlier states will first produce the same matches as in earlier runs. These same old matches will be identified by line 11 as `isoOldStates` and thus ignored. However, this requires the computation of a certificate and an isomorphism check. To avoid this effort, our real implementation of the Promote Improvement mode stores the number of already created successors for each state and on reconsideration, this number of rule applications is directly ignored.

4 Performance Results

Figure 3 shows the CRAIndex we achieve for the different input models and the time our best algorithm needed to compute this.

	Input A	Input B	Input C	Input D	Input E
CRA Index	3	3,75	2,94	0,49	0,43
Performance	00:00.412	00:00.665	04:14.479	32:11.173	04:56.309
